Introduction

Networks have become ubiquitous. Communication networks, financial transaction networks, networks describing physical systems, and social networks are all becoming increasingly important in our day-to-day life. Often, we are interested in models of how objects in the network influence each other (e.g., who infects whom in an epidemiological network), or we might want to predict an attribute of interest based on observed attributes of objects in the network (e.g., predicting political affiliations based on online purchases and interactions), or we might be interested in identifying important links in the network (e.g., in communication networks). In most of these scenarios, an important step in achieving our final goal, that either solves the problem completely or in part, is to classify the objects in the network.

Given a network and an object o in the network, there are three distinct types of correlations that can be utilized to determine the classification or label of o:

1. The correlations between the label of o and the observed attributes of o.
2. The correlations between the label of o and the observed attributes (including observed labels) of objects in the neighborhood of o.
3. The correlations between the label of o and the unobserved labels of objects in the neighborhood of o.

Collective classification refers to the combined classification of a set of interlinked objects using all three types of information described above. Note that, sometimes the phrase *relational classification* is used to denote an approach that concentrates on classifying network data by using only the first two types of correlations listed above. However, in many applications that produce data with correlations between labels of interconnected objects (a phenomenon sometimes referred to as *relational autocorrelation* [37]) labels of the objects in the neighborhood are often unknown as well. In such cases, it becomes necessary to simultaneously infer the labels for all the objects in the network.

Within the machine learning community, classification is typically done on each object independently, without taking into account any underlying network that connects the objects. Collective classification does not fit well into this setting. For instance, in the webpage classification problem where webpages are interconnected with hyperlinks and the task is to assign each webpage with a label that best indicates its topic, it is common to assume that the labels on interconnected webpages are correlated. Such interconnections occur naturally in data from a variety of applications such as bibliographic data [10, 16], email networks [7] and social networks [37]. Traditional classification techniques would ignore the correlations represented by these interconnections and would be hard pressed to produce the classification accuracies possible using a collective classification approach.

Even though traditional exact inference algorithms such as *variable elimination* [64, 11] and the *junction tree algorithm* [20] harbor the potential to perform collective classification, they are practical only when the graph structure of the network satisfies certain conditions. In general, exact inference is known to be an NP-hard problem and, to the best of our knowledge, there is no guarantee that real-world network data satisfy the conditions that make exact inference tractable for collective classification. As a consequence, most of the research in collective classification has been devoted to the development of *approximate inference algorithms*.

In this article we provide an introduction to four popular approximate inference algorithms used for collective classification, *iterative classification*, *Gibbs sampling*, *loopy belief propagation* and *mean-field relaxation labeling*. We provide an outline of the basic algorithms by providing pseudo-code, explain how one could apply them to real-world data, provide theoretical justifications (if there exist any), and discuss issues such as feature construction and various heuristics that may lead to improved classification accuracy. We provide case studies, on both real-world and synthetic data, to demonstrate the strengths and weaknesses of these approaches. All of these algorithms have a rich history of development and application to various problems relating to collective classification and we provide a brief discussion of this when we examine related work. Collective classification has been an active field of research for the past decade and as a result, there are numerous other approximate inference algorithms besides the four we describe here. We provide pointers to these works in the related work section. In the

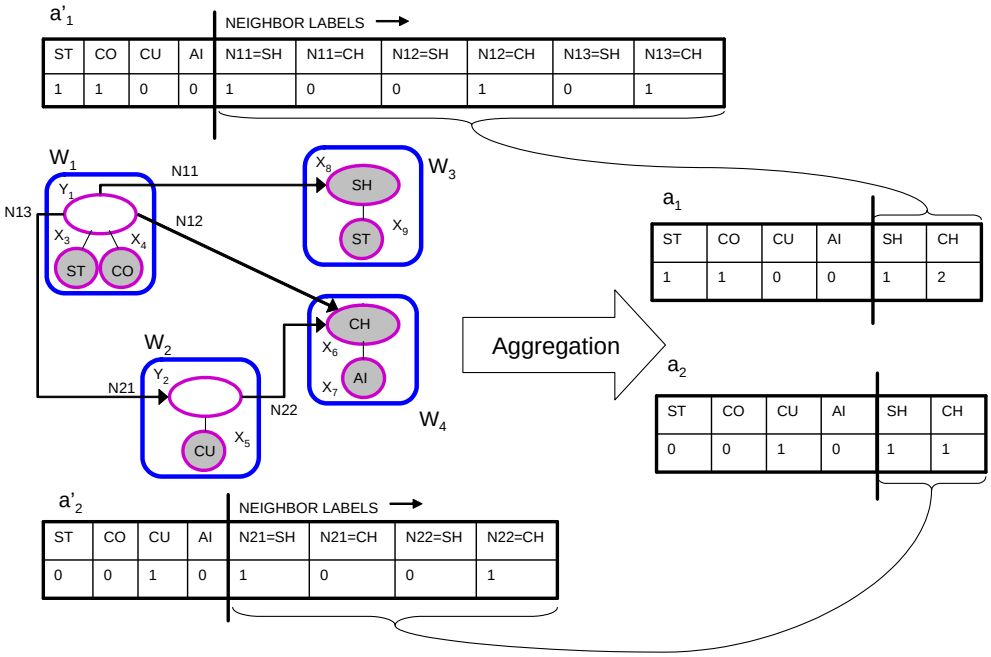

Figure 1: A small webpage classification problem. Each box denotes a webpage, each directed edge between a pair of boxes denotes a hyperlink, each oval node denotes a random variable, each shaded oval denotes an observed variable whereas an unshaded oval node denotes an unobserved variable whose value needs to be predicted. Assume that the set of label values is $\mathcal{L} = \{'SH', 'CH'\}$. The figure shows a snapshot during a run of ICA. Assume that during the last ICA labeling iteration we chose the following labels: $y_1 =' SH'$ and $y_2 =' CH'$. a'_1 and a'_2 show what may happen if we try to encode the respective values into vectors naively, i.e., we get varied-length vectors. The vectors a_1 and a_2 obtained after applying `count` aggregation shows one way of getting around this issue to obtain fixed-length vectors. See text for more explanation.

next section, we begin by introducing the required notation and define the collective classification problem formally.

Collective Classification: Notation and Problem Definition

Collective classification is a combinatorial optimization problem, in which we are given a set of nodes, $\mathcal{V} = \{V_1, \ldots, V_n\}$ and a neighborhood function $\mathcal{N}$, where $\mathcal{N}_i \subseteq \mathcal{V} \setminus \{V_i\}$, which describes the underlying network structure. Each node in $\mathcal{V}$ is a random variable that can take a value from an appropriate domain. $\mathcal{V}$ is further divided into two sets of nodes: $\mathcal{X}$, the nodes for which we know the correct values (observed variables) and, $\mathcal{Y}$, the nodes whose values need to be determined. Our task is to label the nodes $Y_i \in \mathcal{Y}$ with one of a small number of labels, $\mathcal{L} = \{L_1, \ldots, L_q\}$; we'll use the shorthand y_i to denote the label of node Y_i.

We explain the notation further using a webpage classification example that will serve as a running example throughout the article. Figure 1 shows a network of webpages with hyperlinks. In this example, we will use the words (and phrases) contained in the webpages as local attributes. For brevity, we abbreviate the local attributes, thus, 'ST' stands for "student", 'CO' stands for "course", 'CU' stands for "curriculum" and 'AI' stands for "Artificial Intelligence". Each webpage is indicated by a box, the corresponding topic of the webpage is indicated by an ellipse inside the box, and each word in the webpage is represented using a circle inside the box. The observed random variables $\mathcal{X}$ are shaded whereas the unobserved ones $\mathcal{Y}$ are not. We will assume that the domain of the unobserved label variables $\mathcal{L}$, in this case, is a set of two values: "student homepage" (abbreviated to 'SH') and "course homepage" (abbreviated to 'CH'). Figure 1 shows a network with two unobserved variables (Y_1 and Y_2), which require prediction, and seven observed variables (X_3, X_4, X_5, X_6, X_7, X_8 and X_9). Note that some of the observed variables happen to be labels of webpages (X_6 and X_8) for which we know the correct values. Thus, from the figure, it is easy to see that the webpage W_1, whose unobserved label variable is represented by Y_1, contains two words 'ST' and 'CO' and hyperlinks to webpages W_2, W_3 and W_4.

As mentioned in the introduction, due to the large body of work done in this area of research, we have a number of approaches for collective classification. At a broad level of abstraction, these approaches can be divided into two distinct types, one where we use a collection of unnormalized local conditional classifiers and two, where we define the collective classification problem as one global objective function to be optimized. We next describe these two approaches and, for each approach, we describe two approximate inference algorithms. For each topic of discussion, we will try to men-

for each node $Y_i \in \mathcal{Y}$ **do** // bootstrapping
  // compute label using only observed nodes in $\mathcal{N}_i$
  compute $\vec{a}_i$ using only $\mathcal{X} \cap \mathcal{N}_i$
  $y_i \leftarrow f(\vec{a}_i)$
end for
repeat // iterative classification
  generate ordering $\mathcal{O}$ over nodes in $\mathcal{Y}$
  for each node $Y_i \in \mathcal{O}$ **do**
    // compute new estimate of y_i
    compute $\vec{a}_i$ using current assignments to $\mathcal{N}_i$
    $y_i \leftarrow f(\vec{a}_i)$
  end for
until all class labels have stabilized or a threshold number of iterations have elapsed

Approximate Inference Algorithms for Approaches based on Local Conditional Classifiers

Two of the most commonly used approximate inference algorithms following this approach are the *iterative classification algorithm* (ICA) and *gibbs sampling* (GS), and we next describe these in turn.

Iterative Classification

The basic premise behind ICA is extremely simple. Consider a node $Y_i \in \mathcal{Y}$ whose value we need to determine and suppose we know the values of all the other nodes in its neighborhood $\mathcal{N}_i$ (note that $\mathcal{N}_i$ can contain both observed and unobserved variables). Then, ICA assumes that we are given a local classifier f that takes the values of $\mathcal{N}_i$ as arguments and returns the best label value for Y_i from the class label set $\mathcal{L}$. For local classifiers f that do not return a class label but a goodness/likelihood value given a set of attribute values and a label, we simply choose the label that corresponds to the maximum goodness/likelihood value; in other words, we replace f with $\text{argmax}_{l \in \mathcal{L}} f$. This makes the local classifier f an extremely flexible function and we can use anything ranging from a decision tree to an SVM in its place. Unfortunately, it is rare in practice that we know all values in $\mathcal{N}_i$ which is why we need to repeat the process iteratively, in each iteration, labeling each Y_i using the current best estimates of $\mathcal{N}_i$ and the local classifier f, and continuing to do so until the assignments to the labels stabilize.

Most local classifiers are defined as functions whose argument consists of one fixed-length vector of attribute values. Going back to the example we introduced in the last section in Figure 1, assume that we are looking at a snapshot of the state of the labels after a few ICA iterations have elapsed and the label values assigned to Y_1 and Y_2 in the last iteration are 'SH' and 'CH', respectively. $\vec{a}'_1$ in Figure 1 denotes one attempt to pool all values of $\mathcal{N}_1$ into one vector. Thus, the first entry in $\vec{a}'_1$ is a '1' denoting that Y_1 has a neighbor that is the word 'ST' (X_3). Since $Y_2 \in \mathcal{N}_1$, the label value for Y_2 ('CH') is also encoded into $\vec{a}'_1$ but this is done using two entries, $N13 = SH$ is assigned '0' and $N13 = CH$ is assigned '1', where $N13$ denotes the edge connecting Y_1 to Y_2. Unfortunately, since Y_1 and Y_2 have a different number of neighbors, this type of encoding results in $\vec{a}'_1$ consisting of a different number of entries than $\vec{a}'_2$. Since the local classifier can take only vectors of a fixed length, this means we cannot use the same local classifier to classify both $\vec{a}'_1$ and $\vec{a}'_2$.

A common approach to circumvent such a situation is to use an aggregation operator such as `count`. Figure 1 also shows two other vectors $\vec{a}_1$ and $\vec{a}_2$ that are obtained by applying the `count` operator to $\vec{a}'_1$ and $\vec{a}'_2$, respectively. The `count` operator simply counts the number of neighbors assigned 'SH' and 'CH' and adds these entries to the vectors. Thus we get one new value for each entry in the set of label values. Assuming that the set of label values does not change from one unobserved node to another, this results in fixed-length vectors which can now be classified using the same local classifier. Thus, for instance, $\vec{a}_1$ contains two entries, besides the entries corresponding to the local word attributes, encoding that Y_1 has one neighbor labeled 'SH' (X_8) and 2 neighbors currently labeled 'CH' (Y_2 and X_6). Algorithm 1 depicts the ICA algorithm as pseudo-code where we use $\vec{a}_i$ to denote the vector encoding the values in $\mathcal{N}_i$ obtained after aggregation. Note that in the first ICA iteration, all labels y_i are undefined and to initialize them we simply apply the local classifier to the observed attributes in the neighborhood of Y_i, this is referred to as "bootstrapping" in Algorithm 1.

Gibbs Sampling

Gibbs sampling (GS) [18] is widely regarded as one of the most accurate approximate inference procedures. It was originally proposed in Geman & Geman [15] in the context of image restoration. Unfortunately, it is also very slow and some of the common issues while implementing GS is to determine when the procedure has converged. Even though there are tests that can help one determine convergence, they are usually too expensive or complicated to implement.

Due to the issues with traditional GS, researchers in collective classification [42, 33, 35] have developed a lightweight version of it that is easy to implement and faster than traditional GS. The basic idea behind this algorithm is to assume, just like in the case of ICA, that we have access to a local classifier f that can sample for the best label estimate for Y_i given all the values for the nodes in $\mathcal{N}_i$. We keep doing this repeatedly for a fixed number of iterations (a period known as "burn-in"). After that, not only do we sample for labels for each $Y_i \in \mathcal{Y}$ but we also maintain count statistics as to how many times we sampled label l for node Y_i. After collecting a predefined number of such samples we output the best label assignment for node Y_i by choosing the label that was assigned the maximum number of times to Y_i while collecting samples. The pseudo-code for GS is shown in Algorithm 2. For all our experiments (that we report later) we set burn-in to 200 iterations and collected 1000 samples.

for each node $Y_i \in \mathcal{Y}$ **do** // bootstrapping
  // compute label using only observed nodes in $\mathcal{N}_i$
  compute $\vec{a}_i$ using only $\mathcal{X} \cap \mathcal{N}_i$
  $y_i \leftarrow f(\vec{a}_i)$
end for
for n=1 to B **do** // burn-in
  generate ordering $\mathcal{O}$ over nodes in $\mathcal{Y}$
  for each node $Y_i \in \mathcal{O}$ **do**
    compute $\vec{a}_i$ using current assignments to $\mathcal{N}_i$
    $y_i \leftarrow f(\vec{a}_i)$
  end for
end for
for each node $Y_i \in \mathcal{Y}$ **do** // initialize sample counts
  for label $l \in \mathcal{L}$ **do**
    $c[i, l] = 0$
  end for
end for
for n=1 to S **do** // collect samples
  generate ordering $\mathcal{O}$ over nodes in $\mathcal{Y}$
  for each node $Y_i \in \mathcal{O}$ **do**
    compute $\vec{a}_i$ using current assignments to $\mathcal{N}_i$
    $y_i \leftarrow f(\vec{a}_i)$
    $c[i, y_i] \leftarrow c[i, y_i] + 1$
  end for
end for
for each node $Y_i \in \mathcal{Y}$ **do** // compute final labels
  $y_i \leftarrow \text{argmax}_{l \in \mathcal{L}} c[i, l]$
end for

Algorithm 2: Gibbs sampling algorithm

Feature Construction and Further Optimizations

One of the benefits of both ICA and GS is the fact that it is fairly simple to plug in any local classifier. Table 1 depicts the various local classifiers that have been used in the past. There is some evidence to indicate that some local classifiers tend to produce higher accuracies than others, at least in the application domains where such experiments have been conducted. For instance, Lu & Getoor [32] report that on bibliography datasets and webpage classification problems logistic regression outperforms naïve Bayes.

Recall that, to represent the values of $\mathcal{N}_i$, we described the use of an aggregation operator. In the example, we used `count` to aggregate values of the labels in the neighborhood but `count` is by no means the only aggregation operator available. Past research has used a variety of aggregation operators including `minimum`, `maximum`, `mode`, `exists` and `proportion`. Table 2 depicts various aggregation operators and the systems that used these operators. The choice of which aggregation operator to use depends on the application domain and relates to the larger question of *relational feature construction* where we are interested in determining which features to use so that classification accuracy is maximized. In particular, there is some evidence to indicate that new attribute values derived from the graph structure of the network in the data, such as the *betweenness centrality*, may be beneficial to the accuracy of the classification task [14]. Within the inductive logic programming community, aggregation has been studied as a means for propositionalizing a relational classification problem [25, 26, 27]. Within the Statistical Relational Learning community, Perlich and Provost [44, 45] have studied aggregation extensively and Popescul & Ungar [46] have worked on statistical predicate invention.

McDowell, Gupta, & Aha [35]	naïve Bayes, k-nearest neighbors

Table 1: Summary of local classifiers used by previous work in conjunction with ICA and GS.

Other aspects of ICA that have been the subject of investigation include the ordering strategy to determine in which order to visit the nodes to relabel in each ICA iteration. There is some evidence to suggest that ICA is fairly robust to a number of simple ordering strategies such as random ordering, visiting nodes in ascending order of diversity of its neighborhood class labels and labeling nodes in descending order of label confidences [17]. However, there is also some evidence that certain modifications to the basic ICA procedure tend to produce improved classification accuracies. For instance, both Neville & Jensen [40] and McDowell, Gupta, & Aha [35] propose a strategy where only a subset of the unobserved variables are utilized as inputs for feature construction. More specifically, in each iteration, they choose the top-k most confident predicted labels and use only those unobserved variables in the following iteration's predictions, thus ignoring the less confident predicted labels. In each subsequent iteration they increase the value of k so that in the last iteration all nodes are used for prediction. McDowell et al. report that such a "cautious" approach leads to improved accuracies.

Approximate Inference Algorithms for Approaches based on Global Formulations

An alternate approach to performing collective classification is to define a global objective function to optimize. In what follows, we will describe one common way of defining such an objective function and this will require some more notation.

We begin by defining a *pairwise Markov random field* (pairwise MRF) [51]. Let $G = (\mathcal{V}, E)$ denote a graph of random variables as before where $\mathcal{V}$ consists of two types of random variables, the unobserved variables, $\mathcal{Y}$, which need to be assigned values from label set $\mathcal{L}$, and observed vari-

	aggr. operators
PRMs, Friedman *et al.* [12]	`mode`, `count`, SQL
RMNs, Taskar, Abbeel, & Koller [51]	`mode`, SQL
MLNs, Richardson & Domingos [47]	FOL
Lu & Getoor [32]	`mode`, `count`, `exists`
Macskassy & Provost [33]	`prop`
Gupta, Diwan, & Sarawagi [19]	`mode`, `count`
McDowell, Gupta, & Aha [35]	`prop`

Table 2: A list of systems and the aggregation operators they use to aggregate neighborhood class labels. `Mode` is the most common class label, `prop` is the proportion of each class in the neighborhood, `count` is the number of each class label, and `exists` is an indicator for each class label. SQL denotes the standard structured query language for databases and all aggregation operators it includes and, FOL stands for first order logic.

ables $\mathcal{X}$ whose values we know. Let Ψ denote a set of *clique potentials*. Ψ contains three distinct types of functions:

- For each $Y_i \in \mathcal{Y}$, $\psi_i \in \Psi$ is a mapping $\psi_i : \mathcal{L} \rightarrow \Re_{\geq 0}$, where $\Re_{\geq 0}$ is the set of non-negative real numbers.
- For each $(Y_i, X_j) \in E$, $\psi_{ij} \in \Psi$ is a mapping $\psi_{ij} : \mathcal{L} \rightarrow \Re_{\geq 0}$.
- For each $(Y_i, Y_j) \in E$, $\psi_{ij} \in \Psi$ is a mapping $\psi_{ij} : \mathcal{L} \times \mathcal{L} \rightarrow \Re_{\geq 0}$.

Let $\mathbf{x}$ denote the values assigned to all the observed variables in G and let x_i denote the value assigned to X_i. Similarly, let $\mathbf{y}$ denote any assignment to all the unobserved variables in G and let y_i denote a value assigned to Y_i. For brevity of notation we will denote by ϕ_i the clique potential obtained by computing $\phi_i(y_i) = \psi_i(y_i) \prod_{(Y_i,X_j)\in E} \psi_{ij}(y_i)$. We are now in a position to define a pairwise MRF.

Definition 1. *A pairwise Markov random field (MRF) is given by a pair $\langle G, \Psi \rangle$ where G is a graph and Ψ is a set of clique potentials with ϕ_i and ψ_{ij} as defined above. Given an assignment $\mathbf{y}$ to all the unobserved variables $\mathcal{Y}$, the pairwise MRF is associated with the probability distribution $P(\mathbf{y}|\mathbf{x}) = \frac{1}{\mathcal{Z}(\mathbf{x})} \prod_{Y_i \in \mathcal{Y}} \phi_i(y_i) \prod_{(Y_i,Y_j)\in E} \psi_{ij}(y_i, y_j)$ where $\mathbf{x}$ denotes the observed values of $\mathcal{X}$ and $\mathcal{Z}(\mathbf{x}) = \sum_{\mathbf{y}'} \prod_{Y_i \in \mathcal{Y}} \phi_i(y'_i) \prod_{(Y_i,Y_j)\in E} \psi_{ij}(y'_i, y'_j)$.*

The above notation is further explained in Figure 2 where we augment the running example introduced earlier by adding clique potentials. MRFs are defined on undirected graphs and thus we have dropped the directions on all the hyperlinks in the example. In Figure 2, ψ_1 and ψ_2 denote two clique potentials defined on the unobserved variables (Y_1 and Y_2) in the network. Similarly, we have one ψ defined for each edge that involves at least one unobserved variable as an end-point. For instance, ψ_{13} defines a mapping from $\mathcal{L}$ (which is set to $\{SH, CH\}$ in the example) to non-negative real numbers. There is only one edge between the two unobserved variables in the network and this edge is associated with the clique potential ψ_{12} that is a function over two arguments. Figure 2 also shows how to compute the ϕ clique potentials. Essentially, given an unobserved variable Y_i, one

collects all the edges that connect it to observed variables in the network and multiplies the corresponding clique potentials along with the clique potential defined on Y_i itself. Thus, as the figure shows, $\phi_2 = \psi_2 \times \psi_{25} \times \psi_{26}$.

Given a pairwise MRF, it is conceptually simple to extract the best assignments to each unobserved variable in the network. For instance, we may adopt the criterion that the

for each $(Y_i, Y_j) \in E(G)$ s.t. $Y_i, Y_j \in \mathcal{Y}$ **do**
  for each $y_j \in \mathcal{L}$ **do**
    $m_{i \to j}(y_j) \leftarrow 1$
  end for
end for
repeat // perform message passing
  for each $(Y_i, Y_j) \in E(G)$ s.t. $Y_i, Y_j \in \mathcal{Y}$ **do**
    for each $y_j \in \mathcal{L}$ **do**
      $m_{i \to j}(y_j) \leftarrow \alpha \sum_{y_i} \psi_{ij}(y_i, y_j)\phi_i(y_i) \prod_{Y_k \in \mathcal{N}_i \cap \mathcal{Y} \setminus Y_j} m_{k \to i}(y_i)$
    end for
  end for
until all $m_{i \to j}(y_j)$ stop showing any change
for each $Y_i \in \mathcal{Y}$ **do** // compute beliefs
  for each $y_i \in \mathcal{L}$ **do**
    $b_i(y_i) \leftarrow \alpha\phi_i(y_i) \prod_{Y_j \in \mathcal{N}_i \cap \mathcal{Y}} m_{j \to i}(y_i)$
  end for
end for

Algorithm 3: Loopy belief propagation

best label value for Y_i is simply the one corresponding to the highest marginal probability obtained by summing over all other variables from the probability distribution associated with the pairwise MRF. Computationally however, this is difficult to achieve since computing one marginal probability requires summing over an exponentially large number of terms which is why we need approximate inference algorithms.

We describe two approximate inference algorithms in this paper and both of them adopt a similar approach to avoiding the computational complexity of computing marginal probability distributions. Instead of working with the probability distribution associated with the pairwise MRF directly (Definition 1) they both use a simpler "trial" distribution. The idea is to design the trial distribution so that once we fit it to the MRF distribution then it is easy to extract marginal probabilities from the trial distribution (as easy as reading off the trial distribution). This is a general principle which forms the basis of a class of approximate inference algorithms known as *variational methods* [23].

We are now in a position to discuss *loopy belief propagation* (LBP) and *mean-field relaxation labeling* (MF).

Loopy Belief Propagation

Loopy belief propagation (LBP) applied to pairwise MRF $\langle G, \Psi \rangle$ is a message passing algorithm that can be concisely expressed as the following set of equations:

$$m_{i \to j}(y_j) = \alpha \sum_{y_i \in \mathcal{L}} \psi_{ij}(y_i, y_j)\phi_i(y_i) \prod_{Y_k \in \mathcal{N}_i \cap \mathcal{Y} \setminus Y_j} m_{k \to i}(y_i), \quad \forall y_j \in \mathcal{L} \quad (1)$$

$$b_i(y_i) = \alpha\phi_i(y_i) \prod_{Y_j \in \mathcal{N}_i \cap \mathcal{Y}} m_{j \to i}(y_i), \ \forall y_i \in \mathcal{L} \quad (2)$$

where $m_{i \to j}$ is a message sent by Y_i to Y_j and α denotes a normalization constant that ensures that each message and each set of marginal probabilities sum to 1, more precisely,

for each $Y_i \in \mathcal{Y}$ **do** // initialize messages
  for each $y_i \in \mathcal{L}$ **do**
    $b_i(y_i) \leftarrow 1$
  end for
end for
repeat // perform message passing
  for each $Y_j \in \mathcal{Y}$ **do**
    for each $y_j \in \mathcal{L}$ **do**
      $b_j(y_j) \leftarrow \alpha\phi_j(y_j) \prod_{Y_i \in \mathcal{N}_j \cap \mathcal{Y}, y_i \in \mathcal{L}} \psi_{ij}^{b_i(y_i)}(y_i, y_j)$
    end for
  end for
until all $b_j(y_j)$ stop changing

Algorithm 4: Mean-field relaxation labeling

$\sum_{y_j} m_{i \to j}(y_j) = 1$ and $\sum_{y_i} b_i(y_i) = 1$. The algorithm proceeds by making each $Y_i \in \mathcal{Y}$ communicate messages with its neighbors in $\mathcal{N}_i \cap \mathcal{Y}$ until the messages stabilize (Eq. (1)). After the messages stabilize, we can calculate the marginal probability of assigning Y_i with label y_i by computing $b_i(y_i)$ using Eq. (2). The algorithm is described more precisely in Algorithm 3. Figure 2 shows a sample round of message passing steps followed by LBP on the running example.

LBP has been shown to be an instance of a variational method. Let $b_i(y_i)$ denote the marginal probability associated with assigning unobserved variable Y_i the value y_i and let $b_{ij}(y_i, y_j)$ denote the marginal probability associated with labeling the edge (Y_i, Y_j) with values (y_i, y_j). Then Yedidia, Freeman, & Weiss [61] showed that the following choice of trial distribution,

$$b(\mathbf{y}) = \frac{\prod_{(Y_i, Y_j) \in E} b_{ij}(y_i, y_j)}{\prod_{Y_i \in \mathcal{Y}} b_i(y_i)^{|\mathcal{Y} \cap \mathcal{N}_i| - 1}}$$

and subsequently minimizing the Kullback-Liebler divergence between the trial distribution from the distribution associated with a pairwise MRF gives us the LBP message passing algorithm with some qualifications. Note that the trial distribution explicitly contains marginal probabilities as variables. Thus, once we fit the distribution, extracting the marginal probabilities is as easy as reading them off.

Relaxation Labeling via Mean-Field Approach

Another approximate inference algorithm that can be applied to pairwise MRFs is *mean-field relaxation labeling*

(MF). The basic algorithm can be described by the following fixed point equation:

$$b_j(y_j) = \alpha\phi_j(y_j) \prod_{Y_i \in \mathcal{N}_j \cap \mathcal{Y}} \prod_{y_i \in \mathcal{L}} \psi_{ij}^{b_i(y_i)}(y_i, y_j), \quad y_j \in \mathcal{L}$$

where $b_j(y_j)$ denotes the marginal probability of assigning $Y_j \in \mathcal{Y}$ with label y_j and α is a normalization constant that ensures $\sum_{y_j} b_j(y_j) = 1$. The algorithm simply computes the fixed point equation for every node Y_j and keeps doing so until the marginal probabilities $b_j(y_j)$ stabilize. When they do, we simply return $b_j(y_j)$ as the computed marginals. The pseudo-code for MF is shown in Algorithm 4.

MF can also be justified as a variational method in almost exactly the same way as LBP. In this case, however, we choose a simpler trial distribution:

$$b(\mathbf{y}) = \prod_{Y_i \in \mathcal{Y}} b_i(y_i)$$

We refer the interested reader to Weiss [57], Yedidia, Freeman, & Weiss [61] for more details.

Experiments

In our experiments, we compared the four collective classification algorithms (CC) discussed in the previous sections and a content-only classifier (CO), which does not take the network into account, along with two choices of local classifiers on document classification tasks. The two local classifiers we tried were naïve Bayes (NB) and Logistic Regression (LR). This gave us 8 different classifiers: CO with NB, CO with LR, ICA with NB, ICA with LR, GS with NB, GS with LR, MF and LBP. The datasets we used for the experiments included both real-world and synthetic datasets.

Features used

For CO classifiers, we used the words in the documents for observed attributes. In particular, we used a binary value to indicate whether or not a word appears in the document. In ICA and GS, we used the same local attributes (i.e., words) followed by `count` aggregation to count the number of each label value in a node's neighborhood. Finally, for LBP and MF, we used pairwise Markov Random Fields with clique potentials defined on the edges and unobserved nodes in the network.

Experimental Setup

Due to the fact that we are dealing with network data, traditional approaches to experimental data preparation such as creating splits for k-fold cross-validation may not be directly applicable. Splitting the dataset into k subsets randomly and using $k-1$ of them for training leads to splits where $\frac{k-1}{k}$ portion of the neighborhood of a test node are labeled. When k is reasonably high (say, 10) then this will result in almost the entire neighborhood of a test node being labeled. If we were to experiment with such a setup, we would not be able to compare how well the CC algorithms exploit the correlations between the unobserved labels of the connected nodes.

To construct splits whose neighbors are unlabeled as much as possible, we developed a strategy that we call snowball sampling evaluation strategy (SS). In this strategy, we construct splits for test data by randomly selecting the initial node and expanding around it. We do not expand randomly; instead, we select nodes based on the class distribution of the whole corpus; that is, the test data is stratified. The nodes selected by the SS are used as the test set while the rest is used for training. We repeat this process k times to obtain k test-train pairs of splits. Our SS strategy is explained in greater detail in Algorithm 5. Besides experimenting on test splits created using SS, we also experimented with splits created using the standard k-fold cross-validation methodology.

```
Randomly select and add initial node to S
Add all nodes linked to the initial node to a list P
i = 1
while i < numNodesPerSample do
  Sample label l from label distribution
  while node of label l does not exists in P do
    Add all nodes linked to the nodes in P to P
    if nodes were not added in the last step then
      Discard split and restart using a new initial node
    end if
  end while
  Randomly select a node n of label l in P
  Add n to S
  i ← i + 1
end while
```

Algorithm 5: Snowball sampling split creation

where we choose nodes randomly to create splits and refer to this as RS.

When using SS, some of the objects may appear in more than one test split. In that case, we need to adjust accuracy computation so that we do not over count those objects. A simple strategy is to average the accuracy for each instance first and then take the average of the averages. Further, to help the reader compare the SS results with the RS results, we also provide accuracies averaged per instance and across all instances that appear in at least one SS split. We denote these numbers using the term matched cross-validation (M).

Learning the classifiers

One aspect of the collective classification problem that we have not discussed so far is how to learn the various classifiers described in the previous sections. Learning refers to the problem of determining the parameter values for the local classifier, in the case of ICA and GS, and the entries in the clique potentials, in the case of LBP and MF, which can then be subsequently used to classify unseen test data. For all our experiments, we learned the parameter values from fully labeled datasets created through the splits generation methodology described above using gradient-based optimization approaches. Unfortunately, a full treatment of this subject is not possible within this article and we refer the interested reader to various other works that discuss this in more depth such as Taskar, Abbeel, & Koller [51], Sen &

Dataset	RS	SS
Cora-Train	0.10	0.11
Cora-Test	0.09	0.40
Citeseer-Train	0.10	0.07
Citeseer-Test	0.10	0.51

Table 3: Percent unlabeled nodes in the neighborhood. Snowball sampling produces test data which has instances with a higher proportion of unlabeled neighborhood.

Getoor [48], Sen & Getoor [49].

Real-world Datasets

We experimented with three real-world datasets: Cora and CiteSeer (two bibliographic datasets), and WebKB (a hypertext dataset). For the WebKB experiments, we only considered documents which link to or are linked to by at least one other webpage in the corpus. This gave us a corpus of size 877 documents divided into the four standard university splits (after discarding the "other" split) containing webpages from Cornell, Texas, Wisconsin and Washington. We also performed stemming and stop word removal to obtain a vocabulary with 1703 distinct words. There are 1608 hyperlinks in the dataset with 5 class labels. Note that webpages from one university do not link to webpages from the other universities, which means that while performing four-fold cross-validation using the university splits, we can only use the words in the webpages to seed the inference process with. There are no observed labels to bootstrap the inference. This is not the case with Cora and CiteSeer datasets.

The *Cora* dataset contains a number of Machine Learning papers divided into one of 7 classes while the CiteSeer dataset has 6 class labels. For both datasets, we performed stemming and stop word removal besides removing the words with document frequency less than 10. The final corpus has 2708 documents, 1433 distinct words in the vocabulary and 5429 links, in the case of Cora, and 3312 documents, 3703 distinct words in the vocabulary and 4732 links in the case of CiteSeer. For each dataset, we performed both RS evaluation (with 10 splits) and SS evaluation (averaged over 10 runs).

Results We first compare the percentage of unlabeled data in the neighborhood of nodes in the training and test splits created using SS and RS. The numbers are shown in Table 3. The amount of unlabeled data in the neighborhood of a test node is 4-5 times higher for SS compared to RS.

The accuracy results for the real world datasets are shown in Table 4, Table 5 and Table 6. The accuracies are separated by sampling method and base classifier. The highest accuracy at each partition is in bold. We performed t-test (paired where applicable, and Welch t-test otherwise) to test statistical significance between results. Here are the main results:

1. Do CC algorithms improve over CO counterparts?

   In all three datasets, CC algorithms outperformed their CO counterparts, in all evaluation strategies (SS, RS and M). The performance differences were significant for all comparisons except for the NB (M) results for Citeseer.

2. Does the choice of the base classifier affect the results of the CC algorithms?

   We observed a similar trend for the comparison between NB and LR. LR (and the CC algorithms that used LR as a base classifier) outperformed NB versions in all datasets, and the difference was statistically significant for both WebKB and Cora.

3. Is there any CC algorithm that dominates the other?

   The results for comparing CC algorithms are less clear. In the NB partition, the difference between ICA-NB and GS-NB was not significant for WebKB, ICA-NB outperformed GS-NB significantly for Cora using SS and M, and GS-NB outperformed ICA-NB for Citeseer SS. Thus, there was no clear winner between ICA-NB and GS-NB in terms of performance. In the LR portion, again the differences between ICA-LR and GS-LR were not significant for all datasets. As for LBP and MF, they outperformed ICA-LR and GS-LR most of the time, but the

Algorithm	4-fold
CO-NB	0.7030
ICA-NB	0.7215
GS-NB	**0.7234**
CO-LR	0.7734
ICA-LR	0.7956
GS-LR	**0.7969**
LBP	**0.8446**
MF	**0.8446**

Table 4: Accuracy results for WebKB. CC algorithms outperformed their CO counterparts significantly, and LR versions outperformed NB versions significantly. The differences between ICA-NB and GS-NB, and the differences between ICA-LR and GS-LR are not statistically significant. Both LBP and MF outperformed ICA-LR and GS-LR significantly.

Algorithm	SS	RS	M
CO-NB	0.7285	0.7776	0.7476
ICA-NB	**0.8054**	**0.8478**	**0.8271**
GS-NB	0.7613	0.8404	0.8154
CO-LR	0.7356	0.7695	0.7393
ICA-LR	0.8457	0.8796	0.8589
GS-LR	**0.8495**	**0.8810**	**0.8617**
LBP	0.8554	0.8766	0.8575
MF	**0.8555**	**0.8836**	**0.8631**

Table 5: Accuracy results for the Cora dataset. CC algorithms outperformed their CO counterparts significantly. LR versions significantly outperformed NB versions. ICA-NB outperformed GS-NB for SS and M, the other differences between ICA and GS were not significant (both NB and LR versions). Even though MF outperformed ICA-LR, GS-LR, and LBP, the differences were not statistically significant.

Algorithm	SS	RS	M
CO-NB	0.7427	0.7487	0.7646
ICA-NB	0.7540	**0.7683**	**0.7752**
GS-NB	**0.7596**	0.7680	0.7737
CO-LR	0.7334	0.7321	0.7532
ICA-LR	**0.7629**	**0.7732**	0.7812
GS-LR	0.7574	0.7699	**0.7843**
LBP	**0.7663**	**0.7759**	0.7843
MF	0.7657	0.7732	**0.7888**

Table 6: Accuracy results for the Citeseer dataset. CC algorithms significantly outperformed their CO counterparts except for ICA-NB and GS-NB for matched cross-validation. CO and CC algorithms based on LR outperformed the NB versions, but the differences were not significant. ICA-NB outperformed GS-NB significantly for SS; but, the rest of the differences between LR versions of ICA and GS, LBP, and MF were not significant.

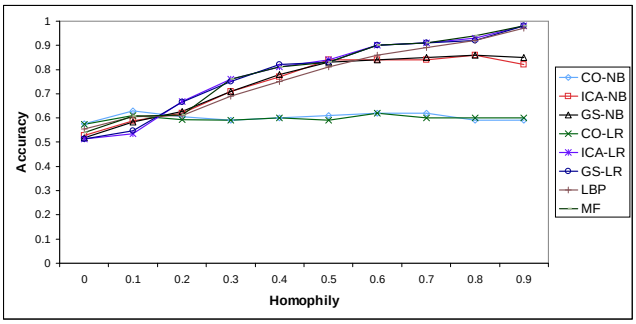

Figure 3: Accuracy of algorithms through different values for dh varying the levels of homophily. When the homophily is very low, both CO and CC algorithms perform equally well but as we increase homophily, CC algorithms improve over CO classifier.

differences were not significant for Cora and Citeseer.

4. How do SS results and RS results compare?

   Finally, we take a look at the numbers under the columns labeled M. First, we would like to remind the reader that even though we are comparing the results on the test set that is the intersection of the two evaluation strategies (SS and RS), different training data could have been potentially used for each test instance, thus the comparison can be questioned. Nonetheless, we expected the matched cross-validation results (M) to outperform SS results simply because each instance had more labeled data around it from RS splitting. The differences were not big (around 1% or 2%); however, they were significant. These results tell us that the evaluation strategies can have a big impact on the final results, and care must be taken while designing an experimental setup for evaluating CC algorithms on network data [13].

Synthetic Data

We implemented a synthetic data generator following Sen and Getoor [49]. A coarse pseudo-code is given in Algorithm 6 for completeness, but more details can be found in Sen & Getoor.

$i = 1$
while $i = 1 <$ numNodes **do**
  Sample r uniformly random from $[0, 1)$.
  if $r < ld$ **then**
    Pick a source node $node_s$
    Pick a destination node $node_d$ based on dh and degree
    Add a link between $node_s$ and $node_d$
  else
    Generate a node $node_i$
    Sample a class for $node_i$
    Sample attributes for $node_i$ using a binomial distribution. Introduce noise to the process based on the attribute noise parameter.
    Connect it to a destination node based on dh and degree
    $i \leftarrow i + 1$
  end if
end while

Algorithm 6: Synthetic data generator

At each step, we either add a link between two existing nodes or create a node based on the ld parameter (such that higher ld value means higher link density, i.e., more links in the graph) and link this new node to an existing node. When we are adding a link, we choose the source node randomly but we choose the destination node using the dh parameter (which varies homophily [37] by specifying what percentage, on average, of a node's neighbor is of the same type) as well as the degree of the candidates (preferential attachment [3]). When we are generating a node, we sample a class for it and generate attributes based on this class using a binomial distribution. Then, we add a link between the new node and one of the existing nodes, again using the homophily parameter and the degree of the existing nodes. In all of these experiments, we generated 1000 nodes, where each node is labeled with one of 5 possible class labels and has 10 attributes. We experimented with varying degree of homophily and link density in the graphs generated.

Results The results for varying values of dh, homophily, are shown in Figure 3. When homophily in the graph was low, both CO and CC algorithms performed equally well, which was expected result based on similar work. As we increased the amount of homophily, all CC algorithms drastically improved their performance over CO classifiers. With homophily at dh=.9, for example, the difference between our best performing CO algorithm and our best performing CC algorithm is about 40%. Thus, for datasets which demonstrate some level of homophily, using CC can significantly improve performance.

We present the results for varying the ld, link density, parameter in Figure 4. As we increased the link density of

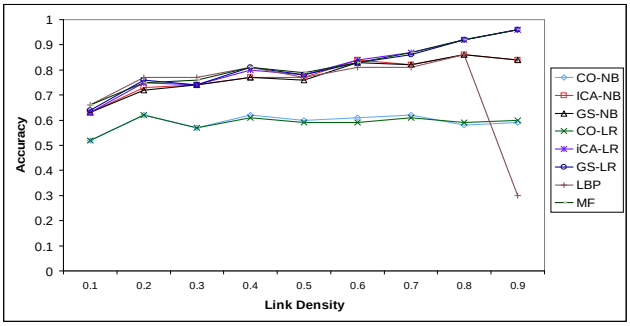

Figure 4: Accuracy of algorithms through different values for ld varying the levels of link density. As we increase link density, ICA and GS improve their performance the most. Next comes MF. However, LBP has convergence issues due to increased cycles and in fact performs worse than CO for high link density.

the graphs, we saw that accuracies for all algorithms went up, possibly because the relational information became more significant and useful. However, the LBP accuracy had a sudden drop when the graph was immensely dense. The reason behind this result is the well known fact that LBP has convergence issues when there are many closed loops in the graph [41].

Practical Issues

In this section, we discuss some of the practical issues to consider when applying the various CC algorithms. First, although MF and LBP perform consistently better than ICA and GS, they were also the most difficult to work with in both learning and inference. Choosing the initial weights so that the weights will converge during training is non-trivial. Most of the time, we had to initialize the weights with the weights we got from ICA in order to get the algorithms to converge. Thus, the MF and LBP had unfair advantages in the above experiments. We also note that of the two, we had the most trouble with MF being unable to converge, or when it did, not converging to the global optimum. Our difficulty with MF and LBP are consistent with previous work [56, 39, 60] and should be taken into consideration when choosing to apply these algorithms.

Second, ICA and GS parameter initializations worked for all datasets we used and we did not have to tune the initializations for these two algorithms. They were the easiest to train and test among all the collective classification algorithms evaluated.

Third, ICA and GS produced very similar results for almost all experiments. However, ICA is a much faster algorithm than GS. In our largest dataset, Citeseer, for example, ICA-NB took 14 minutes to run while GS-NB took over 3 hours. The large difference is due to the fact that ICA converges in just a few iterations, whereas GS has to go through significantly more iterations per run due to the initial burn-in stage (200 iterations), as well as the need to run a large number of iterations to get a sufficiently large sampling (800 iterations).

Related Work

Even though collective classification has gained attention only in the past five to seven years, the general problem of inference for structured output spaces has received attention for a considerably longer period of time from various research communities including computer vision, spatial statistics and natural language processing. In this section, we attempt to describe some of the work that is most closely related to the work described in this article, however, due to the widespread interest in collective classification our list is sure to be incomplete.

One of the earliest principled approximate inference algorithms, *relaxation labeling* [21], was developed by researchers in computer vision in the context of object labeling in images. Due to its simplicity and appeal, relaxation labeling was a topic of active research for some time and many researchers developed different versions of the basic algorithm [31]. Mean-field relaxation labeling [56, 61], discussed in this article, is a simple instance of this general class of algorithms. Besag [5] also considered statistical analysis of images and proposed a particularly simple approximate inference algorithm called *iterated conditional modes* which is one of the earliest descriptions and a specific version of the *iterative classification algorithm* presented in this article. Besides computer vision, researchers working with an iterative decoding scheme known as "Turbo Codes" [4] came up with the idea of applying Pearl's belief propagation algorithm [43] on networks with loops. This led to the development of the approximate inference algorithm that we, in this article, refer to as *loopy belief propagation* (LBP) (also known as *sum product* algorithm) [28, 36, 29].

Another area that often uses collective classification techniques is document classification. Chakrabarti, Dom, & Indyk [8] was one of the first to apply collective classification to a corpora of patents linked via hyperlinks and reported that considering attributes of neighboring documents actually hurts classification performance. Slattery & Craven [50] also considered the problem of document classification by constructing features from neighboring documents using an *Inductive Logic Programming* rule learner. Yang, Slattery, & Ghani [59] conducted an in-depth investigation over multiple datasets commonly used for document classification experiments and identified different patterns. Since then, collective classification has also been applied to various other applications such as part-of-speech tagging [30], classification of hypertext documents using hyperlinks [51], link prediction in friend-of-a-friend networks [52], optical character recognition [54], entity resolution in sensor networks [9], predicting disulphide bonds in protein molecules [53], segmentation of 3D scan data [2] and classification of email "speech acts" [7].

Besides the four approximate inference algorithms discussed in this article, there are other algorithms that we did not discuss such as graph-cuts based formulations [6], formulations based on linear programming relaxations [24, 55] and expectation propagation [38]. Other examples of approximate inference algorithms include algorithms devel-

oped to extend and improve loopy belief propagation (LBP) to remove some of its shortcomings such as alternatives with convergence guarantees [63] and alternatives that go beyond just using edge and node marginals to compute more accurate marginal probability estimates such as the cluster variational method [62], junction graph method [1] and region graph method [61].

More recently, there have been some attempts to extend collective classification techniques to the semi-supervised learning scenario [58, 34].

Conclusion

In this article, we gave a brief description of four popular collective classification algorithms. We explained the algorithms, showed how to apply them to various applications using examples and highlighted various issues that have been the subject of investigation in the past. Most of the inference algorithms available for practical tasks relating to collective classification are approximate. We believe that a better understanding of when these algorithms perform well will lead to more widespread application of these algorithms to more real-world tasks and that this should be a subject of future research. Most of the current applications of these algorithms have been on homogeneous networks with a single type of unobserved variable that share a common domain. Even though extending these ideas to heterogeneous networks is conceptually simple, we believe that a further investigation into techniques that do so will lead to novel approaches to feature construction and a deeper understanding of how to improve the classification accuracies of approximate inference algorithms. Collective classification has been a topic of active research for the past decade and we hope that more articles such as this one will help more researchers gain introduction to this area thus promoting further research into the understanding of existing approximate inference algorithms and perhaps help develop new, improved inference algorithms.
